The spectroscopic and photophysical properties of [Ru(bpy)$_3$]$_2$[Mo$_{18}$O$_{54}$(SO$_4$)$_2$], where bpy is 2,2'-bipyridyl and [Mo$_{18}$O$_{54}$(SO$_4$)$_2$]$^{4-}$ is either the $\alpha$ or $\beta$-sulfite containing polyoxomolybdate isomer, have been measured and compared with those for the well known but structurally distinct sulfate analogue, $\alpha$-[Mo$_{18}$O$_{54}$(SO$_4$)$_2$]$^{4-}$. Electronic difference spectroscopy revealed the presence of new spectral features around 480 nm, although they are weak in comparison with the [Ru(bpy)$_3$]$_2$[Mo$_{18}$O$_{54}$(SO$_4$)$_2$] analogue. Surprisingly, Stern–Volmer plots of [Ru(bpy)$_3$]$_2^+$ luminescence quenching by the polyoxometallate revealed the presence of both static and dynamic quenching for both $\alpha$ and $\beta$-[Mo$_{18}$O$_{54}$(SO$_4$)$_2$]$^{4-}$. The association constant inferred for the ion cluster [Ru(bpy)$_3$]$_2$[Mo$_{18}$O$_{54}$(SO$_4$)$_2$] is $K = 5.9 \pm 0.56 \times 10^6$ and that for [Ru(bpy)$_3$]$\beta$-[Mo$_{18}$O$_{54}$(SO$_4$)$_2$] is $K = 1.0 \pm 0.09 \times 10^7$. Unlike the sulfate polyoxometalates, both sulfite polyoxometalate–ruthenium adducts are non-luminescent. Despite the strong electrostatic association in the adducts resonance Raman and photoelectrochemical studies suggests that unlike the sulfato polyoxometalate analogue there is no sensitization of the polyoxometalate photochemistry by the ruthenium centre for the sulfite anions. In addition, the adducts exhibit photochemical lability in acetonitrile, attributable to decomposition of the ruthenium complex, which has not been observed for other [Ru(bpy)$_3$]$_2^+$-polyoxometalate adducts. These observations suggest that less electronic communication exists between the [Ru(bpy)$_3$]$_2^+$ and the sulfite polyoxoanions relative to their sulfate polyoxoanion counterparts, despite their structural and electronic analogy. The main distinction between sulfate and sulfite polyoxometalates lies in their reversible reduction potentials, which are more positive by approximately 100 mV for the sulfite anions. This suggests that the capacity for [Ru(bpy)$_3$]$_2^+$ or analogues to sensitize photoreduction in the adducts of polyoxometalates requires very sensitive redox tuning.

Introduction

Polyoxometalates (POMs) are an important and structurally diverse class of inorganic clusters which have found application across a broad range of disciplines including photocatalysis, medicine, and organic synthesis. In the field of photocatalysis, the Dawson polyoxometalate anions (see Fig. 1) are well known as efficient photocatalysts and are capable of multiple proton coupled redox processes. However, a key limitation is that in their fully oxidised state Dawson polyanions typically only absorb in the UV spectral region restricting their potential use in photovoltaic devices. An attractive but challenging proposition is to sensitize the polyoxometalate light-induced redox processes using a visible absorbing species that is strongly electronically coupled to the polyoxometalate and this has been the focus of recent research by our group and others.

As a result of their well-behaved and predictable redox and photophysical characteristics, [Ru(bpy)$_3$]$_2^+$ and its analogues have been widely applied as photosensitizers in interfacial photovoltaics.
and in supramolecular systems.\textsuperscript{4-9} It was therefore rationalized that they may be useful as sensitizers for polyoxometalate photochemistry as the cationic charge of most ruthenium polypyridyl complexes permits ready association with these anions.\textsuperscript{4-9} This has been exploited both in intermolecular assemblies and in solution. For example, multilayers of a number of polyoxo anions and ruthenium and osmium polypyridyl complexes have been formed electrostatically on both glassy carbon and ITO (indium tin oxide) electrodes.\textsuperscript{4-5} In addition, it has been demonstrated that [Ru(bpy)]\textsuperscript{2+} forms stable electrostatic adducts with the non-reduced Dawson sulfato anions [M\textsubscript{x}O\textsubscript{y}O\textsubscript{z}(SO\textsubscript{4})\textsubscript{2}]\textsuperscript{4-} (where M = Mo, W) to form analytically pure [Ru(bpy)]\textsubscript{2+}[M\textsubscript{x}O\textsubscript{y}O\textsubscript{z}(SO\textsubscript{4})\textsubscript{2}] adducts.\textsuperscript{5-9}

The photophysics of the adducts [Ru(bpy)]\textsubscript{3+}[M\textsubscript{x}O\textsubscript{y}O\textsubscript{z}(SO\textsubscript{4})\textsubscript{2}] (where M = Mo, W) have been thoroughly investigated.\textsuperscript{5-10} These species exhibited a remarkable degree of electronic coupling between the molybdate polypoxidion and [Ru(bpy)]\textsuperscript{2+}. This was reflected in the substantial photochemical stability conferred on the [Ru(bpy)]\textsuperscript{2+} cation when incorporated into the adduct; and the presence of a new optical transition, assigned as an intramolecular charge-transfer transition from resonance Raman spectroscopy, involving both the polypoxidion and the [Ru(bpy)]\textsuperscript{2+} centres. Remarkably, this new cluster complex was luminescent.\textsuperscript{6} Comparable interactions were also observed between the tungsten analogue [W\textsubscript{18}O\textsubscript{54}(SO\textsubscript{4})\textsubscript{2}]\textsuperscript{4-} and [Ru(bpy)]\textsuperscript{2+}.\textsuperscript{6-7} A photochemical study of [Ru(bpy)]\textsubscript{3+}[M\textsubscript{x}O\textsubscript{y}O\textsubscript{z}(SO\textsubscript{4})\textsubscript{2}] (M = Mo, W) demonstrated that the quantum yield of [Ru(bpy)]\textsubscript{3+}[M\textsubscript{x}O\textsubscript{y}O\textsubscript{z}(SO\textsubscript{4})\textsubscript{2}] photoreduction at 420 nm was an order of magnitude higher than that for [M\textsubscript{x}O\textsubscript{y}O\textsubscript{z}(SO\textsubscript{4})\textsubscript{2}] (Hex\textsubscript{x}N = tetrahexylammonium) in the presence of benzyl alcohol substrate.\textsuperscript{8}

The photophysics of ion clusters comprising [Ru(bpy)]\textsuperscript{2+} and lacunary substituted Dawson polyoxotungstates have also been investigated. Seery \textit{et al.} demonstrated that the overall charge of the POM is not the only parameter driving ion-pair formation, as the association constant of [Ru(bpy)]\textsubscript{5+}[P\textsubscript{n}W\textsubscript{17}O\textsubscript{61}(Fe\textsuperscript{3+}.Br\textsuperscript{-})\textsuperscript{7-}]\textsuperscript{-} was orders of magnitude smaller than those for the lacunary substituted clusters [Ru(bpy)]\textsubscript{3+}[P\textsubscript{2}W\textsubscript{15}O\textsubscript{53}(Fe\textsuperscript{3+}.OH\textsuperscript{-})] and [Ru(bpy)]\textsubscript{3+}[P\textsubscript{2}W\textsubscript{15}O\textsubscript{53}(Fe\textsuperscript{3+}.Br\textsuperscript{-})].\textsuperscript{9} The photophysics of adducts of lacunary [P\textsubscript{2}W\textsubscript{15}O\textsubscript{53}(Fe\textsuperscript{3+}.OH\textsuperscript{-})]\textsuperscript{-} and its unsubstituted parent ion [P\textsubscript{2}W\textsubscript{15}O\textsubscript{53}]\textsuperscript{-} has also been investigated with [Ru(bpy)]\textsubscript{3+}(Mebpy–pyl)\textsuperscript{10}. It was found that the bulkier Mebpy–py ligand had reduced the capacity for quenching by the polyoxotungstates, indicating that steric effects may be an important parameter in determining polyoxometalate ruthenium sensitizer interactions.

In this present contribution, the photophysical properties of [Ru(bpy)]\textsubscript{3+} in the presence of the sulfite-containing Dawson-like anions α-β-[Mo\textsubscript{10}O\textsubscript{32}(SO\textsubscript{3})\textsubscript{4}]\textsuperscript{4-} (α-β-[SO\textsubscript{3}-POM) are presented. These relatively new structures were first reported in 2004.\textsuperscript{11} The replacement of conventional sulfate groups with sulfite groups allows for the possibility of intramolecular electronic communication between the encapsulated sulfur atoms, and indeed the α-[SO\textsubscript{3}-POM is more difficult to reduce than the corresponding α-[Mo\textsubscript{10}O\textsubscript{32}(SO\textsubscript{4})\textsubscript{4}]\textsuperscript{4-} (SO\textsubscript{4}-POM) by about 100 mV.\textsuperscript{12} The unusual distribution of charge within the metal oxide framework results in a distortion of the geometry from the standard Dawson anion to the non-conventional “peanut” configuration, which has also been observed in the non-reduced sulfite polyoxotungstate α-[W\textsubscript{10}O\textsubscript{32}(SO\textsubscript{3})\textsubscript{4}]\textsuperscript{4-} and in the tin-substituted [H\textsubscript{3}SnW\textsubscript{18}O\textsubscript{60}]\textsuperscript{-13,14} The sulfite- and sulfate-containing species exhibit similar spectroscopic properties. The structures of α-[Mo\textsubscript{10}O\textsubscript{32}(SO\textsubscript{3})\textsubscript{4}]\textsuperscript{4-} and β-[Mo\textsubscript{10}O\textsubscript{32}(SO\textsubscript{4})\textsubscript{4}]\textsuperscript{4-} are provided in Fig. 1 for comparison.

Although the [Ru(bpy)]\textsuperscript{2+} adducts of α and β-[Mo\textsubscript{10}O\textsubscript{32}(SO\textsubscript{4})\textsubscript{4}]\textsuperscript{4-} have been recently isolated, the spectroscopy and photophysics of these materials have not been studied to date.\textsuperscript{20} The aim of this study, in the context of optimising ruthenium polyoxometalate interactions for sensitized photocatalysis, was to determine how the electronic properties, charge and isomeric structure of these materials influenced their interactions with the [Ru(bpy)]\textsuperscript{2+} sensitizer. Given the improved photocatalysis evident for the anions α-β-[Mo\textsubscript{10}O\textsubscript{32}(SO\textsubscript{4})\textsubscript{4}]\textsuperscript{4-} by comparison with their sulfate analogue (see ESIR) a key objective is to determine if these properties extend to the [Ru(bpy)]\textsuperscript{2+} polyoxometalate adducts.

**Experimental**

**Materials**

Photophysical studies were carried out in aerated spectroscopic grade acetonitrile, dried over activated molecular sieves (3 Å) (Aldrich). Benzyl alcohol (spectroscopic grade, Aldrich) was dried over molecular sieves before use. [Ru(bpy)]\textsubscript{2+}(PF\textsubscript{6})\textsubscript{2} was synthesized as described previously.\textsuperscript{20} [Pn\textsubscript{4}N\textsubscript{4}]/α-β-[Mo\textsubscript{10}O\textsubscript{32}(SO\textsubscript{4})\textsubscript{4}] (Pn\textsubscript{4}N is tetrapotassium), [Hex\textsubscript{3}N\textsubscript{4}]/α-β-[Mo\textsubscript{10}O\textsubscript{32}(SO\textsubscript{4})\textsubscript{4}], and [Ru(bpy)]\textsubscript{3+}/α-β-[Mo\textsubscript{10}O\textsubscript{32}(SO\textsubscript{4})\textsubscript{4}] were synthesised according to literature methods and chemical analyses confirmed the compositions.\textsuperscript{13,18,20} Tetrabutylammonium tetrafluoroborate, lithium perchlorate and tetrabutylammonium hexafluorophosphate (Aldrich) were used as purchased. Potassium bromide (Riedel de Haen) was heated to 100 °C overnight, to remove residual water content. Ludox AM-30 was used as purchased (Aldrich). SiO\textsubscript{2}-coated ITO electrodes were used as purchased (Delta Technologies Ltd., Stillwater, MN, USA).

**Methods**

UV/Vis absorption spectra were obtained using a Varian Cary UV 50 Scan spectrophotometer. Steady state emission measurements were undertaken using a Cary Eclipse Fluorescence spectrometer with 10 nm emission and 10 nm excitation slits exciting at 450 nm. Time-correlated single photon counting (TCSPC) measurements were carried out using a Picoquant ‘Fluotime 100’ compact fluorescence lifetime spectrometer. The 450 nm pulse was generated by Picoquant ‘PDL 800-B’ pulsed diode laser and a Thurlby Thandar Instruments (TTi) TGP110 10 MHz pulse generator. An average of three measurements was taken for each sample, and the data was fitted to a monoexponential model using a reconvolution function. The instrument response function was measured using a scattering Ludox AM-30 colloidal silica solution. Resonance Raman spectra were collected on a Horiba Jobin Yvon HR800 UV spectrometer. The laser lines were generated by a Coherent Innova 70c tuneable Ar-ion laser (457.9, 488, 514.5 nm). A 10x microscope objective was used to focus the laser beam onto a sample ground into a compressed KBr disc or in acetonitrile solution. A 600 lines per mm diffraction grating was employed. The x-axis was calibrated versus the Rayleigh line (0 nm) and the phonon mode from silicon wafer (520 cm\textsuperscript{-1}). Attenuated total reflectance Fourier-Transform infrared (ATR-FTIR) spectroscopy was performed using a Varian 610-IR FTIR.
microscope and a slide-on ATR accessory with a germanium crystal tip. The solid samples were mounted on a clean gold substrate and each spectrum acquired consisted of an average of 256 scans. Photoelectrochemical measurements were carried out using a standard three-electrode system and a CH Instruments 720b electrochemical workstation. The working electrodes were prepared by drop-casting 25 µl of concentrated (1 mM) acetonitrile suspension/solution of the metallo-adduct onto an ITO working electrode and allowing it to dry in air. A large area Pt flag was used as the counter electrode. An Ag wire was employed as the pseudo-reference, which was calibrated versus the IUPAC recommended ferrocene (Fc/Fc⁺) internal reference. The potential was maintained constant at 400 mV throughout the experiment. Neat benzyl alcohol was used as both the solution and sacrificial donor; and no electrolyte was added so as to avoid ion-pair disruption. The light source for photochemistry was an Oriet 68811 arc lamp employing a 350 W Xe bulb and a >400 nm long pass filter, and was kept at a distance of 10 cm from the sample solution. The optical filter was purchased from Spectrogon UK Ltd.

**Results and discussion**

**Absorption spectroscopy**

Strong electronic communication between [Ru(bpy)]³⁺ and polyoxometalate is accompanied by significant modification to the UV/Vis spectroscopy of both species.⁶,⁷,⁸ In order to elucidate the presence of any new optical transitions resulting from the electronic interaction between α or β-[Mo₁₈O₅₄(SO₃)₂]⁴⁻ and [Ru(bpy)]³⁺, difference electronic spectroscopy was used. In this approach, a range of solutions were prepared to investigate the effects of varying polyoxometalate concentration on the spectroscopy of a constant concentration of [Ru(bpy)]³⁺. Each solution contained 7.3 × 10⁻⁶ M [Ru(bpy)]³⁺ in which the concentration of α or β-[Mo₁₈O₅₄(SO₃)₂]⁴⁻ was varied between 1 × 10⁻⁸ M and 3.0 × 10⁻⁴ M in order that the ratio of α or β-[Mo₁₈O₅₄(SO₃)₂]⁴⁻ to [Ru(bpy)]³⁺ encompassed the 1 : 1 and 2 : 1 range. Fig. 2(a) shows the resulting electronic difference spectra generated by subtracting the electronically combined spectra of a polyoxometalate mole fraction (XPOM) of approximately 0.375, which corresponds to a α-[Mo₁₈O₅₄(SO₃)₂]⁴⁻ to [Ru(bpy)]³⁺ ratio of approximately 0.6 : 1. This is in good agreement with the expected value of 0.5 : 1 (XPOM = 0.33) for a complex where the anionic charge on the polyoxometalate is fully compensated for by the dicaticonic ruthenium complex. When the corresponding isomer β-[Mo₁₈O₅₄(SO₃)₂]⁴⁻ was investigated similar behaviour was observed, although the new visible absorbance grew at 479 nm and shifted to 486 nm upon reaching X_POM of 0.29, which again, is close to the expected value of 0.33. These data strongly indicate that [Ru(bpy)]³⁺ associates electrostatically with α/β-[Mo₁₈O₅₄(SO₃)₂]⁴⁻ in a 2 : 1 ratio in acetonitrile.

![Figure 2](image)

Fig. 2 (a) UV/Vis difference spectra of [Ru(bpy)]³⁺ (7.3 × 10⁻⁶ M) upon addition of α-[Mo₁₈O₅₄(SO₃)₂]⁴⁻ (9.9 × 10⁻⁷ M to 4.8 × 10⁻⁴ M) in dry acetonitrile. (b) Job’s plot of absorbance change at 475 nm as a function of α-[Mo₁₈O₅₄(SO₃)₂]⁴⁻ concentration.

The ATR-FTIR spectra of the POMs and their Ru metallo-adducts were obtained (ESI) to identify any structural changes induced in the complexes on association. Modes characteristic of the polyoxomolybdate anion are shifted by between 3 and 8 cm⁻¹ by comparison with the parent anion. For the composite material, polyoxomolybdate modes are observed at 781 cm⁻¹ (Mo–O–Mo involving edge-sharing octahedral), 972 cm⁻¹ (Mo–O–Mo involving corner-sharing octahedral) and 935 cm⁻¹ (Mo=O terminal mode).²¹,²² The sulfite S=O symmetric stretch was observed at 902 cm⁻¹.²¹,²² Interestingly, the metal-oxide stretch at...
781 cm\(^{-1}\) and the out-of-plane C–H bending at 757 cm\(^{-1}\) shift to lower and higher energy, respectively, upon association relative to their parent ion spectra; while the bipyridine out-of-plane ring bending at 730 cm\(^{-1}\) is unaffected.\(^\text{24,25}\) Comparable behaviour has been reported in several other Ru-POM hybrid systems and indicates strong association.\(^\text{26,27}\) Peaks between 1350 and 1500 cm\(^{-1}\) were attributed to the tetrapentylammonium counterion, and the Ru complex PF\(_5^-\) counterion was observed at 835 cm\(^{-1}\) for the parent ions. None of these modes are present in the composite material spectrum, indicating, in agreement with the Job’s plot, that full ion compensation between cation and anion occurs.

**Luminescence studies.** In order to determine the impact of association of \([\text{Mo}_{18}\text{O}_{54}(\text{SO}_3)^2]^{4-}\) on the photophysical properties of \([\text{Ru}(\text{bpy})_3]^{2+}\), the luminescence of this complex was studied as a function of polyoxometalate concentration in dry acetonitrile.

Fig. 3 shows that significant quenching of the \([\text{Ru}(\text{bpy})_3]^{2+}\) MLCT luminescence is observed upon addition of \(\alpha\text{-}[\text{Mo}_{18}\text{O}_{54}(\text{SO}_3)^2]^{4-}\). The \([\text{Ru}(\text{bpy})_3]^{2+}\) phosphorescence centred at 610 nm decreased steadily upon addition of successive quantities of \(\alpha\text{-}[\text{Mo}_{18}\text{O}_{54}(\text{SO}_3)^2]^{4-}\) or \(\beta\text{-}[\text{Mo}_{18}\text{O}_{54}(\text{SO}_3)^2]^{4-}\) as the ions associated, although there was no evidence for a shift in the luminescence \(\lambda_{\text{em}}\). This behaviour contrasts with that of the sulfato polyoxomolybdate \([\text{Mo}_{18}\text{O}_{54}(\text{SO}_4)^2]^{4-}\), where significant changes in the emission maxima and peak shape were evident. A shoulder observed at ~630 nm was attributed to luminescence from the 2:1 associated complex.\(^\text{x}\) Even though a very weak residual luminescence at 610 nm remains when the \(\alpha/\beta\text{-}[\text{Mo}_{18}\text{O}_{54}(\text{SO}_3)^2]^{4-}\) concentration exceeds that of the ruthenium complex by more that 2.5 times, it is likely that this emission arises from unassociated \([\text{Ru}(\text{bpy})_3]^{2+}\) rather than an intrinsic emission from the associated complex. To verify this, the isolated solids \([\text{Ru}(\text{bpy})_3]^{2+}\) were examined using confocal fluorescence microscopy which confirmed that the 2:1 complex is non-emissive in the solid state. The excitation spectra taken for the weak residual emission of the species confirmed that it matched that of \([\text{Ru}(\text{bpy})_3]^{2+}\) suggesting that the any remaining emission arises from unassociated \([\text{Ru}(\text{bpy})_3]^{2+}\).

**Fig. 3** Luminescence quenching of \([\text{Ru}(\text{bpy})_3]^{2+}\) (1.0 \(	ext{×}\) 10\(^{-4}\) M) by addition of the polyoxometalate \(\alpha\text{-}[\text{Mo}_{18}\text{O}_{54}(\text{SO}_3)^2]^{4-}\) (1.6 \(	ext{×}\) 10\(^{-4}\) M to 2.6 \(	ext{×}\) 10\(^{-4}\) M) in dry MeCN.

Comparison of the behaviour of the luminescence intensity and lifetime of \([\text{Ru}(\text{bpy})_3]^{2+}\) as a function of the quencher concentration can yield insights into the nature of the interaction between the two compounds. Dynamic quenching, where interaction between the species is collisional and therefore diffusion controlled, is expected to follow the Stern–Volmer equation (eqn (1)):

\[
\frac{I_0}{I} = 1 + K_{SV}[Q]
\]

where \([Q]\) is the concentration of the quencher; \(I\) is the luminescence intensity; \(\tau\) is the luminescent lifetime of the lumophore; and \(\Phi\) is the luminescence quantum yield. \(K_{SV}\) is the Stern–Volmer constant (eqn (2)):

\[
K_{SV} = k_q \times \tau_0
\]

where \(k_q\) is the experimental rate constant for quenching and \(\tau_0\) is the lifetime of the unquenched fluorophore. For purely static quenching, where a non-luminescent association complex forms between the complex an analogous equation is employed (eqn (3)), but the, slope is now the association constant, \(K\).

\[
\frac{I_0}{I} = 1 + K[Q]
\]

In the case of purely static quenching, leading to a non-emitting association complex, the observed lifetime of the lumophore is expected to be unaffected by quencher concentration, so the \(I_0/I\) or \(\Phi_0/\Phi\) plots vary with quencher concentration but \(\tau_0/\tau\) does not. In a mixed static and dynamic scenario, the lifetime will be affected by quencher concentration, but the slopes of the \(I_0/I\) plot and \(\tau_0/\tau\) plots differ. Consequently, comparison of the luminescence lifetime and intensity as a function of quencher concentration can be used to assess whether quenching is static, dynamic or a combination of both. The \(I_0/I\) plot and \(\tau_0/\tau\) plots for addition of the sulfite polyoxomolybdates to \([\text{Ru}(\text{bpy})_3]^{2+}\) are shown in Fig. 4 and 5.

**Fig. 4** Stern–Volmer plots of the emission quenching of \([\text{Ru}(\text{bpy})_3]^{2+}\) (1.0 \(	ext{×}\) 10\(^{-4}\) M) by \(\alpha\text{-}[\text{Mo}_{18}\text{O}_{54}(\text{SO}_3)^2]^{4-}\) (—) and \(\beta\text{-}[\text{Mo}_{18}\text{O}_{54}(\text{SO}_3)^2]^{4-}\) (●) (1.6 \(	ext{×}\) 10\(^{-4}\) M to 2.6 \(	ext{×}\) 10\(^{-4}\) M) in aerated acetonitrile.

It is perhaps important to remember that the luminophore, \([\text{Ru}(\text{bpy})_3]^{2+}\), is present in excess at the beginning of the experiment and that the formation of the associated complex most likely occurs in the following sequence:

\[
3[\text{Ru}(\text{bpy})_3]^{2+} + [\text{Mo}_{18}\text{O}_{54}(\text{SO}_3)^2]^{4-} \rightleftharpoons [\text{Ru}(\text{bpy})_3][\text{Mo}_{18}\text{O}_{54}(\text{SO}_3)^2] + [\text{Ru}(\text{bpy})_3]^{2+}
\]
Initially, when the ruthenium complex is present in large excess, the 2:1 complex would be expected to form. As shown in Fig. 4, the data is non-linear with significant upward curvature and at least two distinct regions of response, when applied to a Stern–Volmer model, one explanation for such behaviour is that the 2:1 adduct remains luminescent but the 1:1 is not. However, as described above, fluorescence microscopy confirmed this is not the case (ESI†). Upward curvature in the Stern–Volmer plot, i.e. \( \tau / \tau \) versus \([Q]\), for both sulfite isomers, a reduction in \([Ru(bpy)]^{2+}\) lifetime was found to accompany increasing polyoxometalate concentration. In each case, the lifetime fits remained monoeponential. This implies that there is a dynamic component to the quenching of the ruthenium by both sulfite polyoxometalates. The slopes of \( \tau / \tau \) versus \([Q]\) are equal to \( K_{sv} \), according to eqn (1) which are \( 3.1 \times 10^4 \) mol\(^{-1}\) for \( \alpha-[Mo_{10}O_{34}(SO_4)_2]^{6-} \) and \( 2.5 \times 10^6 \) mol\(^{-1}\) for \( \beta-[Mo_{10}O_{34}(SO_4)_2]^{6-} \) over the data range corresponding to a 2:1 \([Ru(bpy)]^{2+}\) : \([Mo_{18}O_{54}(SO_3)_2]^{4-}\) ratio. The dynamic quenching rate constants, \( k_q \), were estimated according to eqn (2) to be \( 1.6 \pm 0.2 \times 10^{11} \) L mol\(^{-1}\) s\(^{-1}\) and \( 1.9 \pm 0.10 \times 10^{11} \) L mol\(^{-1}\) s\(^{-1}\) for the \( \alpha \) and \( \beta \) isomers respectively, these exceeded the diffusion controlled rate (approx. \( 10^{10} \) L mol\(^{-1}\) s\(^{-1}\)) which is consistent with dynamic quenching which contains a static contribution.

A modified form of the emission Stern–Volmer eqn (6) can be used for mixed static and dynamic quenching, the parameters are as explained above:

\[
\frac{I}{I_0} = 1 + (K_{sv} + K_q)[Q] + K_{sv}K_q[Q]^2
\]  

(6)

Therefore, plotting \((I_0/I) - 1)/[POM] \) vs. \([POM] \) gave a plot with a slope equal to \( K_{sv} \times K_q \). Since the \( K_{sv} \) values were obtained from lifetime data, \( K_q \) values were derived from these fits as \( 5.9 \pm 0.56 \times 10^4 \) and \( 1.0 \pm 0.09 \times 10^4 \) for the \( \alpha \) and \( \beta \) isomers respectively (see ESI†). The \( K_{sv} \) value obtained for the association of the corresponding 2:1 sulfate polyoxometalate complex with \([Ru(bpy)]^{2+}\) was \( 1 \times 10^{10} \); this suggests the sulfite polyoxomolybdate analogue has a slightly higher affinity for \([Ru(bpy)]^{2+}\) compared with sulfato. Importantly, these earlier studies indicated that the charge on the polyoxometalate was not solely responsible for the magnitude of the association constant with \([Ru(bpy)]^{2+}\).  

**Influence of ion-pairing on adduct formation**

To investigate the association between \([Ru(bpy)]^{2+}\) and \( \alpha-[Mo_{10}O_{34}(SO_4)_2]^{6-}\) further, the effect of ionic strength on the associated cluster was examined by studying the luminescence recovery from \([Ru(bpy)]^{2+}\) with increasing salt concentration. It is well known that \( ClO_4^- \) ions have a high propensity to ion-pair with ruthenium polypyridyl complexes, and this salt has been shown to disrupt ion pairing in the case of \([Ru(bpy)]^{2+}\) and other Dawson polyoxometalates.\(^6,7,9\) The impact of LiClO\(_4\) addition to a solution of \([Ru(bpy)]^{2+}\) : \( \beta-[Mo_{10}O_{34}(SO_4)_2]^{6-}\) containing a ten-fold excess of polyoxometalate is shown in ESI†.  

This study shows that by a concentration of \( 9.86 \times 10^{-3} \) M LiClO\(_4\), the luminescence of free \([Ru(bpy)]^{2+}\) was fully recovered. A plot of recovering luminescence intensity as a function of increasing LiClO\(_4\) concentration (see ESI†) exhibited upward curvature which was remarkably similar to that for the addition

![Fig. 5 Luminescent lifetime Stern–Volmer plots of 5.0 \times 10^{-6} M [Ru(bpy)]^{2+} lifetime quenched by \( \alpha-[Mo_{10}O_{34}(SO_4)_2]^{6-} \) (■) and by \( \beta-[Mo_{10}O_{34}(SO_4)_2]^{6-} \) (▲) in MeCN.](image)

![Fig. 6 Photocurrents generated by (a) ([Pn]N)_4-[Mo_{10}O_{34}(SO_4)_2]_2\] and (b) [Ru(bpy)]^{2+}-[Mo_{10}O_{34}(SO_4)_2]_2\] modified ITO electrodes in contact with benzyl alcohol (baselines normalized). Each sample was irradiated for 400 s by light from a 300 W Xe arc lamp with a >400 nm long pass filter (light on 1000 s, light off 1400 s).](image)
of LiClO4 to a solution of [P2W17O61(FeOH2)]7− and [Ru(bpy)3]2+ recorded by Seery et al., although the absolute concentrations used differ. Here a 75-fold excess of LiClO4 over polyoxometalate was required to disrupt the ion–ion association.

The analogous experiment was then repeated with the α isomer. In this case, addition of LiClO4 to a solution of 1 × 10−5 M [Ru(bpy)3]2+ and 1 × 10−4 M α-[Mo10O32(SO3)4]2− only resulted in partial recovery of the [Ru(bpy)3]2+ luminescence, and at high LiClO4 concentrations. A UV/Vis spectrum taken before and after the additions showed that the [Ru(bpy)3]2+, α-[Mo10O32(SO3)4]2− MLCT at ~475 nm had also reduced dramatically in intensity, and the baseline had also shifted. This was attributed to poor solubility of the complex in acetonitrile which caused precipitation in the presence of the salt. This was also observed when TBA BF4 or TBA PF6 was employed. The origin of this difference in solubility observed for the two isomers is unknown as they are isoelectronic and isostuctural.

Resonance Raman spectroscopy. The new absorbance formed around 475 nm in the UV-vis spectrum, on the basis of comparison with other clusters, is thought to arise from a new inter-metal charge-transfer within the cluster. In order to confirm this, resonance Raman spectroscopy was conducted of the isolated charge-transfer within the cluster. In order to confirm this, resonance Raman spectroscopy was conducted of the isolated electroreduced polyanion (see ESI†). Their intensity continued to increase with additional addition of LiClO4 concentrations. A UV/Vis spectrum taken before and after the additions showed that the [Ru(bpy)3]2+, α-[Mo10O32(SO3)4]2− MLCT at ~475 nm had also reduced dramatically in intensity, and the baseline had also shifted. This was attributed to poor solubility of the complex in acetonitrile which caused precipitation in the presence of the salt. This was also observed when TBA BF4 or TBA PF6 was employed. The origin of this difference in solubility observed for the two isomers is unknown as they are isoelectronic and isostuctural.

Photochemical stability. Previous studies have demonstrated that [Ru(bpy)3]2+, normally quite photolabile in acetonitrile, becomes exceptionally photochemically stable when associated with a Dawson polyoxoanion.65,67 This was attributed to the strong electronic perturbation of the ruthenium centre by the polyoxometalate. Given the relatively weak electronic interaction indicated here between the sulfite polyoxometalates it is important to see if this influences the photostability of the [Ru(bpy)3]2+ centre. Photochemical stability studies of the novel cluster complexes in acetonitrile were performed using a 300 W Xe arc lamp with a <400 nm optical cut-off filter. The impact of 4 h irradiation of approximately 1 × 10−5 M of [Ru(bpy)3]2+, β-[Mo10O32(SO3)4]2−, [Ru(bpy)3]2+, β-[Mo10O32(SO3)4]2− and [Ru(bpy)3]2+ in acetonitrile were compared. In each instance the samples were absorbance matched over the excitation window. Photochemically induced changes in the complexes were monitored by UV/Vis spectroscopy during the course of the photolysis. Over four hours of irradiation approximately 8% of the intensity of the [Ru(bpy)3]2+ MLCT absorbance was lost for [Ru(bpy)3]2+, β-[Mo10O32(SO3)4]2−, compared with 18% from [Ru(bpy)3]2+, α-[Mo10O32(SO3)4]2−. The photolability of the [Ru(bpy)3]2+ cation in MeCN is well known, and in comparison an absorbance matched (~1 × 10−5 M) solution of [Ru(bpy)3]2+ showed a decrease in MLCT absorbance of approximately 30%. Interestingly, for both sulfite polyoxometalates, the photostability of the complex had increased compared to the control. However comparison with the adduct of the sulfate analogue reveals that this complex exhibited no decomposition at the ruthenium centre under the same conditions. This is again consistent with reduced electronic interaction between the sulfite polyoxometalates and the ruthenium centre. As the ruthenium centre is non-luminescent when associated with the sulfite polyoxometalates, the origin of the modestly increased photostability of the ruthenium centre in the adduct may be kinetic, due to the reduced lifetime of the excited state of this centre. Attempts to measure the excited state lifetime of both [Ru(bpy)3]2+, β-[Mo10O32(SO3)4]2− and [Ru(bpy)3]2+, α-[Mo10O32(SO3)4]2− by transient spectroscopy showed that it was below 15 ns, the resolution of our instrument.

Photo-electrochemistry. The presence of an inter-complex charge-transfer transition in previous Dawson polynuclearate and polytungstate-[Ru(bpy)3]2+ adducts was implicated in the ability of the [Ru(bpy)3]2+ unit to sensitize the photocatalytic activity...
of these polyoxometalates. For example, for \([\text{Mo}_{18}\text{O}_{54}\text{(SO}_3\text{)}]^{4-}\) dissolved in DMF, the quantum yield of photocatalysis was increased substantially under visible irradiation in the presence of the ruthenium cation.\(^6\)

Initial photoelectrochemical studies of \([(\text{Pn})_4\text{N}]\alpha-[\text{Mo}_{18}\text{O}_{54}\text{(SO}_3\text{)}]_2\) and \([\text{Ru(bpy)}]_2\alpha-[\text{Mo}_{18}\text{O}_{54}\text{(SO}_3\text{)}]_2\) were carried out on an ITO electrode using benzyl alcohol as the donor. The samples were prepared by drop casting the composite onto the electrode. In the case of the pure polyoxometalate, a relatively uniform thin film was formed but the 2:1 Ru-POM layer did not deposit as evenly. The modified ITO electrode was immersed in benzyl alcohol and irradiated with \(400\) nm white light using a long pass filter. In order to ensure that the ion-pair remained associated, the photoelectrochemical experiments were performed in the absence of any added supporting electrolyte. The absence of electrolyte meant that IR drop is significant, nonetheless photocatalytic current could be observed. The potential was held at \(0.4\) V to ensure that following photoreduction of polyoxometalate by the benzyl alcohol (eqn (7) and (8)), the reduced polyoxometalate (eqn (8)) was reoxidised back to \([\text{Mo}_{18}\text{O}_{54}\text{(SO}_3\text{)}]^{4-}\) at the working electrode to generate photocatalytic current.

\[
[\text{Mo}_{18}\text{O}_{54}\text{(SO}_3\text{)}]^{4-} + h\nu \rightarrow [\text{Mo}_{18}\text{O}_{54}\text{(SO}_3\text{)}]^{4+}\tag{7}
\]

\[
[\text{Mo}_{18}\text{O}_{54}\text{(SO}_3\text{)}]^{4+} + \text{C}_6\text{H}_5\text{CH}_2\text{OH} \rightarrow [\text{Mo}_{18}\text{O}_{54}\text{(SO}_3\text{)}]^{3-} + \text{C}_6\text{H}_5\text{CH}_2\text{OH} + \text{H}^+\tag{8}
\]

The results of this experiment, shown in Fig. 6, are striking in that both samples generate substantial photocurrents under irradiation with visible light. However, photocurrent generation by the polyoxometalate anion was disappointingly reduced by approximately \(60\%\) in the presence of \([\text{Ru(bpy)}]_2\alpha-[\text{Mo}_{18}\text{O}_{54}\text{(SO}_3\text{)}]_2\) (reduction from \(61.2\) nA to \(23.9\) nA). The reduction in photocurrent confirms that in the case of the sulfite polyoxometalate, the ruthenium does not sensitize the polyoxometalate. The reduction of photocurrent in the presence ruthenium is attributed to the filtering of the incident light by the ruthenium absorbance. Comparison with the \(\beta\)-isomer revealed a slightly higher photocurrent (73.5 nA) for the parent, compared with the \(\alpha\) form under identical conditions. The associated species, \([\text{Ru(bpy)}]_2\beta-[\text{Mo}_{18}\text{O}_{54}\text{(SO}_3\text{)}]_2\), also generated a higher current than the \(\alpha\) analogue, producing \(52\) nA at the electrode. Interestingly the reduction in current when the Ru was present was not as severe as in the \(\alpha\)-isomer case (approximately a \(30\%\) decrease relative to \(60\%\) for the \(\alpha\) experiments).

Conclusions

The photophysics of \([\text{Ru(bpy)}]_2\alpha\) in the presence of the Dawson-like polyoxomolybdates \(\alpha-[\text{Mo}_{18}\text{O}_{54}\text{(SO}_3\text{)}]^{4+}\) and \(\beta-[\text{Mo}_{18}\text{O}_{54}\text{(SO}_3\text{)}]^{4+}\) have been studied. Both anions associate strongly with \([\text{Ru(bpy)}]_2\alpha\) to form adducts which from UV-vis spectroscopy form with approximately \(2:1\) ratio Ru-POM. Surprisingly, unlike other \([\text{Ru(bpy)}]_2\) polyoxoanion studies, the quenching of the ruthenium excited state followed mixed static and dynamic behaviour. Difference electronic spectroscopy of the resulting adducts revealed the presence of a weak new electronic transition which was red-shifted with respect to the \([\text{Ru(bpy)}]_2\) MLCT centred at \(450\) nm which was weaker in intensity and blue shifted compared to a similar absorbance in the sulfato anions. Resonance Raman spectroscopy, exciting into this new transition, did not show the anticipated resonantly enhanced Mo-O modes seen for the sulfato analogues which have been attributed to an inter-complex transition. Photo-electrochemical measurements on ITO electrodes with white light irradiation demonstrated that the associated \([\text{Ru(bpy)}]_2\alpha-[\text{Mo}_{18}\text{O}_{54}\text{(SO}_3\text{)}]_2\), unlike the sulfate analogue \([\text{Pn}_4\text{N}]\alpha-[\text{Mo}_{18}\text{O}_{54}\text{(SO}_3\text{)}]_2\) does not sensitize photocatalytic oxidation of benzyl alcohol. Although the parent sulfite molybdate does exhibit a significantly greater photocurrent from photocatalytic oxidation of benzyl alcohol than the sulfato analogue.
