ABSTRACT: Lacunary polyoxometalates of low nuclearity are difficult to synthesize in isolation. We report the facile synthesis of six $[M_2(\beta$-$SiW_{8}O_{31})_2]$ clusters ($M = $ Co/Mn/Ni/Zn/Cu$^{2+}$/Fe$^{3+}$) that can be employed as building blocks for the formation of larger architectures. We show for the first time that such $[\beta$-$SiW_{9}O_{31}]$ lacunae are capable of reorganizing into larger Keggin lacunary species even in the absence of an external source of tungstate. We hypothesize, based on electrospray ionization mass spectrometry evidence obtained, not only that such a transformation is only possible via an initial decomposition of the $\{SiW_6\}$ precursor into a $\{SiW_5\}$-based intermediate but also that it is this $\{SiW_5\}$ species that acts as the template for the growth of the larger fragments.
water, acidified to pH 6.4 via addition of 4 M HCl or H2SO4. Solution B comprises Kα[β-SiW8O31]·12H2O (1.486 g, 0.5 mmol) and MCl2·XH2O (0.46 mmol) dissolved in 50 mL of 2 M NaCl. Solution A is added to solution B, and the pH is adjusted to 8.8. The resultant mixture is stirred for 20–30 min, depending on the transition metal used. The mixtures are then centrifuged and filtered into 50 mL conical flasks and left at 18 °C to crystallize. Crystals begin to form overnight, and are collected after one week. Average yields are 30–55% based on tungsten, with the exception being the nickel cluster, which only produces a few crystals and could not be optimized.

The architecture is a very simple sandwich structure comprising two {B–β-SiW8} fragments coordinated to two transition metals. The central transition metals coordinate to the complete triads of the lacunary fragment and to an oxygen ligand coming from each silicon heteroatom (see Figure 1).

Figure 1. Polyhedral and ball-and-stick representation of {M2(B–β-SiW8O31)2} cluster. Color scheme: W = teal, M = orange, O = red.

The transition metals have no terminal water ligands, which is unusual for TMSPs. The architecture is very similar to the {M3(H2O)(B–β-XW9O34)(β–XW9O34)} unit found in several TMSPs, however, it is missing one transition metal and one tungsten unit that completes the eclipsed triad of the {B–β-XW9} fragment. Interestingly, the synthetic strategy employed to make the {M2Si2W16} clusters is very similar to the method employed by Mitchell et al. that gave {Co3(H2O)(B–α/B–β-SiW8O31)(B–β-SiW8O31)}, and perhaps it can be postulated that the clusters we report here are intermediates in the formation of such clusters.

All of the compounds crystallize in the space group P1̅ and with almost identical unit cell dimensions. This is unsurprising given that the only difference between the clusters is the transition metal present, and these metal centers are buried at the center of the cluster, not interacting with the sodium cations. The result of this is that the crystal packing is unusual for TMSPs. The architecture is very similar to the {β-XW9} fragment. Interestingly, the synthetic strategy employed to make the {β-XW9} cluster can decompose into a TMSP possessing smaller fragments. Around the main MS envelopes of each charge, described above, are several less-intense signals. These signals correspond to the intact {Cu2Si2W12} cluster (highlighted in black) and fragmented {Cu2Si2W12} species (highlighted in red).

Figure 2. ESI-MS of THA[Cu2(B–β-SiW8O31)2] showing the most intense envelopes for the intact {Cu2Si2W16} (highlighted in black) and fragmented {Cu2Si2W12} species (highlighted in red).

To overcome this, cation exchange was performed, replacing sodium with tetrabutylammonium (THA) to give oily solids, which gave better ionization from acetonitrile solution. Such cationic exchange with bulky tetralkylammonium cations to make POMs organic soluble is known. Mass spectra were attainable for the copper-, cobalt-, and zinc-based clusters (see Figure 2 and Supporting Information). For {Cu2Si2W16}, the intact parent cluster was observable at charge values of −2, −3, −4, and −5 at m/z 3293.6 {KNa(C24H52N)4[Cu2Si2W16Si2O62]·7H2O}2−, 1947.6 {H2Na–(C24H52N)4[Cu2Si2W16Si2O62]·8H2O}3−, 1220.9 {H3KNa–(C24H52N)4[Cu2Si2W16Si2O62]·12H2O}3+, and 1022.9 {H3Na–(C24H52N)4[Cu2Si2W16Si2O62]·7H2O}3− (see Figure 2). This indicates that the cluster is stable enough to withstand the cation exchange process and the ionization conditions. Interestingly, there were envelopes assigned to {Cu2Si2W15} species at −2, −3, −4, and −5 charge at m/z 3178.2 {H3KNa–(C24H52N)4[Cu2Si2W15Si2O62]·9H2O}2−, 1870.2 {H2KNa–(C24H52N)4[Cu2Si2W15Si2O62]·6H2O}3−, 1411.9 {H2Na–(C24H52N)4[Cu2Si2W15Si2O62]·10H2O}4+, and 976.7 {HNa–(C24H52N)4[Cu2Si2W15Si2O62]·8H2O}5+ (see Figure 2). The presence of such {Cu2Si2W15} signals indicates that the cluster can decompose into a TMSP possessing smaller fragments. Around the main MS envelopes of each charge, described above, are several other less-intense signals. These envelopes also correspond to the intact {Cu2Si2W16} cluster and {Cu2Si2W15} fragment but possess different ratios of cations associated with the main POM anion—a common feature of ESI-MS of POMs. Full analysis of these envelopes can be found in the Supporting Information.

It is possible that the decomposition is occurring on just one of the Keggin fragments, but more probable is that each {β–SiW8} is losing the two tungsten units that comprise the incomplete triad, to create a dimer of {SiW6} units. This would keep the central {Cu3} unit intact and retain its original coordination to the completed triads of the POM species. Whether the degradation of the {M3Si2W16} cluster occurs in solution or in the mass spectrometer, the ESI-MS analysis implies a close relationship between the {β–SiW8} and {SiW6} clusters and that the most likely site for decomposition of the...
{β-SiW$_8$} is the incomplete triad. Similar envelopes for the {M$_2$Si$_2$W$_{16}$} and {M$_2$Si$_2$W$_{12}$} species could be identified for the cobalt and zinc clusters. (Full mass spectral analysis can be found in the Supporting Information.)

The {M$_2$Si$_2$W$_{16}$} can be described as an open architecture because within the crystal structure the lacunary sites on the incomplete triad of the {β-SiW$_8$} fragment are vacant, with not even sodium cations occupying the volume close to the central transition metals. In all other examples of TMSPs containing only {B-β-SiW$_8$} fragments,20-22,29,33 the lacunary sites of the tungsten POM are fully occupied, which means that the probability of them reacting further is limited. As the lacunary sites in the {M$_2$Si$_2$W$_{16}$} cluster are vacant, it was hypothesized that these clusters could be used as starting materials in the synthesis of other, hopefully larger, TMSPs. The desire was to discover if these clusters could be used as reliable sources of {B-β-SiW$_8$} fragments in other TMSPs and to observe what structural transformations, if any, could be achieved by lower nuclearity lacunary fragments.

Owing to the fact that the {M$_2$Si$_2$W$_{16}$} architecture was available with several different transition metals, there was a large reaction space to explore. The decision was made to focus on homometallic systems first (i.e., reacting the {M$_2$Si$_2$W$_{16}$} clusters with transition metal (TM) chloride salts such that M = TM) and based upon the findings to then try the more complex heterometallic systems. In the literature, the most abundant metals found coordinated to the {B-β-SiW$_8$} are Cu$^{2+}$ and Co$^{2+}$. Cobalt has a tendency to form trimeric architectures with the {SiW$_6$},22,29 whereas copper has shown the capacity to form dimers,20 trimers,31 and tetramers,21 so initial experiments focused on copper.

The {Cu$_2$Si$_2$W$_{16}$} was dissolved in water, and copper salts were introduced as solutions. Our preliminary experiments involved no external pH control other than that caused by varying the concentration of Cu$^{2+}$ so as to allow the natural equilibria processes to be investigated. It was discovered that at high ratios of {Cu$_2$Si$_2$W$_{16}$}/Cu$^{2+}$ (1:10) the cluster Na$_{16}$[Cu$_{14}$(OH)$_4$(H$_2$O)$_{16}$(B-β-SiW$_{10}$O$_{36}$)$_4$·20.5H$_2$O (Figure 3a) crystallized within two weeks. This is a tetramer of {B-β-SiW$_8$} fragments, previously reported by Zhang et al.21 The formation of this cluster showed that the {M$_2$Si$_2$W$_{16}$} clusters can be used as a source of {B-β-SiW$_8$} in other TMSPs. The structure was confirmed by X-ray diffraction and Fourier transform infrared (FT-IR) analysis. The yield of this reaction was 42%, which is double that of the published procedure; however, the original synthesis directly uses γ-SiW$_{10}$O$_{36}$, so when taking the initial preparation of {Cu$_2$Si$_2$W$_{16}$} into consideration, the yields are comparable. The literature procedure required the addition of d-proline, and similarly to the addition of BHEP in the synthesis of the {Cu$_2$Si$_2$W$_{16}$} starting material, it is not fully understood what exact chemical influence it exerts. This provides further weight to the hypothesis that seemingly spectator organic cations can have significant influence over the reorganization of lacunary POMs.

When a lower ratio of {Cu$_2$Si$_2$W$_{16}$}/Cu$^{2+}$ is employed (1:5), the {Cu$_4$W$_{13}$} cluster still forms within two weeks, albeit as a minor product. Yet, if this mother liquor is left longer, larger, pale blue/green crystals form after one month. These crystals are of the well-documented Weakley-sandwich architecture [Cu$_n$(H$_2$O)$_3$(α-β-SiW$_{10}$O$_{36}$)$_{12-}$]27 Formation of Weakley-sandwich clusters from TMSP reactions is common, but in this instance it was a surprise given that the starting material contains only {β-W$_8$} units and that the Weakley sandwich contains (α-W$_8$) units. There is only one reported case of such a {β-W$_8$}→{α-W$_8$} transformation being observed, but this was within the mother liquor from a reaction that used sodium tungstate as a starting material.32 In the absence of external tungstate, the increase in nuclearity shown within this system is not easy to explain. Examples of other POM fragments growing in nucleus have been reported.33

For the lacunary fragments in this system to grow in size, some free tungstate must be present in solution. The only tungsten within the system is the {M$_2$Si$_2$W$_{16}$} precursor itself, which strongly implies that a level of decomposition of the starting material occurs during the reaction. The most likely site for decomposition is the monovacant eclipsed triad on the {B-β-SiW$_8$} units, as it is not coordinated to the metal centers. Decomposition at this site would be analogous to the manner in which it is proposed {γ-SiW$_{10}$O$_{36}$} initiates its reorganization.30 Such decomposition would result in the formation of {SiW$_6$} lacunae. Given this postulation, there would now be free tungstate in solution, and it has been shown that free tungstate, in the absence of heteroatoms, can form {W$_4$O$_{10}$} Keggin triad-like units.34 It is conceivable that such {W$_4$O$_{10}$} units could recombine with the {SiW$_6$} fragment in such a manner that {B-α-SiW$_8$} fragments could form. (It is worth noting that the most common partner for {SiW$_6$} fragments in TMSPs is {B-α-SiW$_8$}, which implies that there is a strong link between these two species.)23,35 A decomposition→reconstitution mechanism appears the most feasible for explaining both the increase in nuclearity and the change in Keggin isomeric form (see Scheme 1). Via this strategy, the formation of {B-β-SiW$_8$} would also be possible.

As stated above, the ESI-MS analysis of the parent {Cu$_2$Si$_2$W$_{16}$} cluster showed envelopes corresponding to a fragmented {Cu$_2$(SiW$_6$)$_3$} species. This would support the hypothesized decomposition→reconstitution mechanism for the reorganization of {β-SiW$_8$}, as the fragmented {SiW$_6$} units are still coordinated to the central copper ions, and the loss in tungsten could only come from decomposition of the incomplete triads. In the synthesis of the Weakley sandwich cluster from {Cu$_2$Si$_2$W$_{16}$}, based upon the observations made via MS, it is possible to suggest that during the entire transformation, the central two Cu ions remain coordinated to the POM. Hence, this strategy could be used as a route toward the fabrication of mixed TMSPs, by selecting one transition metal in the starting material and introducing a second in solution. With improvements made to the ionization of species in water, it may be possible to follow the POM transformation...
Experimental Section

K$_{2}$[β-SiW$_{12}$O$_{40}$]·12H$_{2}$O was prepared according to the literature procedure. Purity was confirmed by IR analysis. All other chemicals were purchased from SigmaAldrich and used without further purification.

1. Synthesis of [M$_{2}$B-$\beta$-SiW$_{12}$O$_{40}$]$_{n}$ Clusters. 1.1. Synthesis of Na$_{2}$H[Co$_{4}$SiW$_{12}$O$_{40}$]·49H$_{2}$O. BHEP (2.5 g, 1.4 mmol) was dissolved to give a colorless solution (A). The pH of solution A was adjusted to 8.64 using 2 M H$_{2}$SO$_{4}$. In 50 mL of 2 M NaCl solution was dissolved K$_{2}$[β-SiW$_{12}$O$_{40}$]·12H$_{2}$O (1.49 g, 0.5 mmol) and CoCl$_{2}$·6H$_{2}$O (0.110 g, 0.46 mmol), to give a pink/red solution (B). Solution A was added to solution B to give a pink solution, which was adjusted to pH 8.80 via addition of 2 M H$_{2}$SO$_{4}$ dropwise. The resultant solution was stirred for 30 min. After this time the pH was typically 8.7. The solution was filtered into a wide-necked 100 mL conical flask and left in a temperature-controlled environment at 18 °C to crystallize via slow evaporation. Pink needle-shaped crystals obtained overnight. Yield = 0.421 g, 0.079 mmol (31.6% based on W). Characteristic FT-IR (powder) bands (cm$^{-1}$): 3381 (b), 1638 (b), 1125 (m), 970 (w), 855 (sh), 816 (s), 688 (b), 619 (w). UV band: λ = 798 nm, ε = 4.0 M$^{-1}$ cm$^{-1}$. Elemental analysis: H$_{n}$Na$_{2}$Na$_{2}$O$_{31}$Si$_{2}$W$_{16}$ Cu$_{2}$, MW = 5349.16 g mol$^{-1}$. Anal. Calcd (%): W (57.0), Fe (2.17), Na (5.79); found: W (55.3), Fe (2.93), Na (6.41). TGA water loss over 25–450 °C for partially dehydrated H$_{n}$Na$_{2}$Na$_{2}$O$_{31}$Si$_{2}$W$_{16}$ Cu$_{2}$ (%); calculated: 11.7; found: 11.5.

1.5. Synthesis of Na$_{2}$H[Fe$_{5}$SiW$_{10}$O$_{36}$]·42H$_{2}$O. Same method as above, but using FeCl$_{2}$·2H$_{2}$O (0.079 g, 0.46 mmol). Pale blue-green crystals appeared overnight. Yield = 0.487 g, 0.091 mmol (36.4% based on W). Elemental analysis: H$_{n}$Na$_{2}$Na$_{2}$O$_{31}$Si$_{2}$W$_{16}$ Cu$_{2}$, MW = 5336.28 g mol$^{-1}$. Anal. Calcd (%): W (57.0), Fe (2.17), Na (5.79); found: W (55.3), Fe (2.93), Na (6.41). TGA water loss over 25–450 °C for partially dehydrated H$_{n}$Na$_{2}$Na$_{2}$O$_{31}$Si$_{2}$W$_{16}$ Cu$_{2}$ (%); calculated: 11.7; found: 11.5.

1.6. Synthesis of Na$_{2}$H[Fe$_{5}$SiW$_{10}$O$_{36}$]·42H$_{2}$O. Same method as above, but using FeCl$_{2}$·2H$_{2}$O (0.079 g, 0.46 mmol). The solution is initially brown but turns yellow overnight. Dark yellow crystals form directly in ESI-MS experimentation without purification.

2. Formation of Tetrahexylammonium Salts of [M$_{2}$B-$\beta$-SiW$_{12}$O$_{40}$] Clusters for ESI-MS. To 50 mg of [M$_{2}$B-$\beta$-SiW$_{12}$O$_{40}$]$_{n}$ sodium salt, dissolved in 3 mL of deionized water in a test tube was added 100 mg of tetrahexylammonium bromide. An oily residue began to form, and the mixture was left overnight. This residue sank to the bottom. The solvent was decanted off, and the residue was dissolved in 3 mL of MeCN. The residue was reprecipitated by addition of 5 mL of H$_{2}$O, and the solvent was decanted. The reprecipitation was performed a total of three times, and then the oily residue was used directly in ESI-MS experimentation without purification.

3. Use of Na$_{2}$H[Cl$_{2}$Cu$_{4}$SiW$_{8}$O$_{36}$]·14H$_{2}$O as a Starting Material. 3.1. Synthesis of Na$_{2}$H[Cl$_{2}$Cu$_{4}$SiW$_{8}$O$_{36}$]·14H$_{2}$O. To a solution of Na$_{2}$H[Cl$_{2}$SiW$_{12}$O$_{40}$]·49H$_{2}$O (0.100 g, 1.87 × 10$^{-2}$ mmol) in 5 mL of H$_{2}$O, with stirring in a 14 mL vial was added 300 μL of 1 M CuSO$_{4}$·5H$_{2}$O. The resultant blue solution was stirred for 1 h, and then the pH was measured as 3.6. The solution was left directly to crystallize in a temperature-controlled room at 18 °C, without filtering first. After one week blue-green block crystals of the product were visible, but the crystals did not collect until after one month. Yield = 42 mg, 4.2 × 10$^{-3}$ mmol (45% based on W). The compound was confirmed as the published Na$_{2}$H[Cl$_{2}$Cu$_{4}$SiW$_{8}$O$_{36}$]·14H$_{2}$O compound via unit cell checking and IR analysis.

3.2. Synthesis of Na$_{2}$H[Cl$_{2}$Cu$_{4}$SiW$_{8}$O$_{36}$]·3H$_{2}$O. To a solution of Na$_{2}$H[Cl$_{2}$SiW$_{12}$O$_{40}$]·49H$_{2}$O (0.200 g, 3.74 × 10$^{-2}$ mmol) in 10 mL of H$_{2}$O, with stirring in a 14 mL vial was added 90 μL of 1 M CuSO$_{4}$·5H$_{2}$O and 30 μL of H$_{2}$O. The resultant blue solution was stirred for 1 h, and then the pH was measured as 6.6. The solution was left directly to crystallize in a temperature-controlled room at 18 °C, without filtering first. After two months <10 mg of Na$_{2}$H[Cl$_{2}$SiW$_{12}$O$_{40}$]·49H$_{2}$O formed. The mother liquor was left to crystallize for longer, and when the solution was nearly dry, larger pale blue-green crystals formed. Yield = 93 mg, 1.63 × 10$^{-2}$ mmol (48.9% based on W). Characteristic FT-IR (powder) bands (cm$^{-1}$): 3315 (b), 1629 (s) 1135 (w), 1099 (w), 985 (s), 846 (sh), 705 (s), 686 (w), 667 (w), 609 (w). UV band: λ = 757 nm, ε = 4.0 M$^{-1}$ cm$^{-1}$. Elemental analysis: H$_{n}$Na$_{2}$Na$_{2}$O$_{31}$Si$_{2}$W$_{16}$ Cu$_{2}$, MW = 5328.30 g mol$^{-1}$. Anal. Calcd (%): W (55.2), Mn (2.06), Na (6.47); found: W (55.2), Mn (2.06), Na (6.47).

Scheme 1. Proposed Mechanism for the Transformation of {β-$\beta$-SiW$_{12}$} into {α-$\alpha$-SiW$_{12}$} in the Absence of Any External Source of Tungstate

Directly via ESI-MS and further our understanding of how low-nuclearity POMs transform into one another.
CONCLUSIONS

We have reported the facile synthesis of a series of \{B-$\beta$-SiW$_6$O$_{19}\}\)-based TMSP dimers that can be synthesized with many different first-row transition metals. The reaction makes use of BHEP organic base to buffer the reaction. ESI-MS of \{Cu$_4$SiW$_{10}$\} showed that the cluster is stable but can readily fragment into smaller \{SiW$_6$\}-containing dimers. The \{Cu$_4$SiW$_{10}$\} was successfully shown to be a precursor for the synthesis of other TMSPs, one of which was the Weakley sandwich cluster \{Cu$_4$(H$_2$O)(B-$\beta$-SiW$_6$O$_{19}$)$_2$\}. The formation of the Weakley sandwich represents the first reported observation of a direct lacunary Keggin transformation from \{B-$\beta$-SiW$_6$\} in the absence of an external source of tungstate, showing that small lacunary POMs can still undergo significant structural reorganization. We proposed the transformation occurs as follows: (1) Free tungstate was generated by an initial decomposition to \{SiW$_6$\}. (2) The free tungstate assembles into \{W$_3$\} units. (3) The \{SiW$_6$\} recombines with the \{W$_3$\} unit to form the final \{B-$\beta$-SiW$_6$\} species. It is still unclear whether the central copper atoms remain coordinated to the structural reorganization. We proposed the transformation to \{SiW$_6$\}. (2) The free tungstate assembles into \{W$_3$\} units. (3) The \{SiW$_6$\} recombines with the \{W$_3$\} unit to form the final \{B-$\beta$-SiW$_6$\} species. It is still unclear whether the central copper atoms remain coordinated to the structural reorganization.
